Physics of Optoelectronic Devices

Light-Emitting Diodes

This section deals with the principles and characteristics of the technically most important types of visible emitters which are formed, without special lateral structures, as whole-area emitters.

Materials for LEDs

The materials for light-emitting diodes in the visible spectrum (400 - 700 nm) are semiconductors with bandgaps between 1.8 and 3.1 eV, with \( E_g (\text{eV}) = \frac{h \nu}{1240 / \lambda} \) (nm). In order to permit effective recombination, the materials should have direct band-to-band transitions or permit other recombination paths with high efficiency. Neither of these requirements are fulfilled by the well-known semiconductors silicon and germanium, as their bandgaps are too small and they are indirect by nature.

As a further requirement, the materials have to enable manufacturing in the form of monocrystals (volume crystals or at least epitaxial layers) and a sufficiently developed technology must be available for processing.

Element combination from groups III and V of the periodic element system results in semiconducting compounds with bandgaps between 0.18 eV (InSb) and approximately 6 eV (AlN); see figure 1.

For every composition the bandgap is given in eV. Direct semiconductors are denoted by an asterisk. The largest direct bandgaps are found in the group III – nitrides GaN and InN. These nitrides will supercede silicon carbide as semiconducting material for blue light emitting diodes within the next few years. Gallium arsenide has a direct bandgap of 1.42 eV and is not only important for light emitting diodes, but is also a significant substrate material.

III–V compounds can form mixed crystals with properties between those of the binary compounds. The most important mixed crystal systems pertaining to LEDs are GaAs – AlAs, GaAs – GaP, InP – GaP – AlP.

The bandgap and the lattice constant of Ga\(_{1-x}\)Al\(_x\)As and GaAs\(_{1-x}\)P\(_x\) are shown in figure 2. The direct region is shown as a solid line and the indirect region as a dashed line. Up to \( x = 0.44 \) (band gap 1.96 eV), Ga\(_{1-x}\)Al\(_x\)As is direct, and the lattice constant changes only slightly over the whole mixture range. The highest direct bandgap for GaAs\(_{1-x}\)P\(_x\) is 1.99 eV (\( x = 0.45 \)). In the indirect region of GaAs\(_{1-x}\)P\(_x\), the efficiency of radiating recombination can be increased considerably by doping with nitrogen (isoelectronic center). This reduces the effective bandgap by approximately 0.06 eV (second dashed line).

The bandgaps required for common LED colors are marked at the top of figure 2. Whereas red emission can be achieved with Ga\(_{0.6}\)Al\(_{0.4}\)As or GaAs\(_{0.6}\)P\(_{0.4}\) (both direct), the indirect GaAs\(_{1-x}\)P\(_x\) :N is used for the other colors.

In figure 3, the bandgaps and lattice constants of InGaAIP are presented. In this diagram, binary compounds are shown as points, ternary compounds as lines, and the quaternary mixed crystal InGaAIP as a shaded area. The binary crystals InP, GaP and AIP form the apices. Their characteristic form is a result of the complex nature of the band structure and the transition from the direct to the indirect region and vice versa. The diagram shows which InGaAIP compositions are direct and which mixed crystals are lattice matched to a given substrate material. Both are necessary prerequisites for the manufacture of particularly bright light emitting diodes. The vertical dashed line drawn through the direct bandgap region shows the compositions that are exactly lattice matched to, and can be manufactured on a GaAs substrate. The corresponding notation \( \text{In}_{0.5} \text{(Ga}_{x}\text{Al}_{1-x})_{0.5} \text{P} \) gives the ratio of the amounts of atoms in the crystal lattice. The bandgap is direct if the aluminium concentration is below \( x = 0.7 \). The spectral region from red via orange and yellow to green
can be covered by variation of \( x \) in InGaAlP. Extremely high luminescent efficiencies for orange and yellow are obtained in double heterostructures of InGaAlP situated on a Bragg reflector on a GaAs substrate.

Technologies

The figures below show two structures on a GaAs substrate: figure 4, standard red and figure 5, DH-red. Standard red consists of GaAs$_{0.6}$P$_{0.4}$ which was deposited with a GaAs$_{1-x}$P$_x$ buffer layer on a n-GaAs substrate by vaporphase epitaxy. The element is manufactured in a planar process with masked Zn diffusion. The substrate is opaque in this case. This means that the rear contact can be provided over the complete area.

![Figure 4. Standard red](image1)

The DH-red element consists of three epitaxial layers on p-GaAs substrate. The active layer with 35% Al-content is manufactured between two layers of Ga$_{1-x}$Al$_x$As of > 60% Al content.

![Figure 5. DH-red](image2)

Other standard LEDs are shown in figures 6 and 7. The chips for orange and yellow are similar to the standard red type. Due to the large amount of P, 0.6 or 0.85, the material is deposited with suitable buffer layers on the transparent GaP substrate, and a reflective rear contact is provided. The green element consists entirely of GaP and can therefore be manufactured with liquid-phase epitaxy. The grown PN junction is divided by mesa etching in this example to enable measurement of individual chips on the wafer.

![Figure 6. Orange and yellow](image3)

A new type of LED for applications where a particularly high brightness is required is shown in figure 8. The structure is similar to that of a DH-red element. A double heterostructure is arranged on a light-absorbing GaAs substrate. A combination of a Bragg reflector between the substrate and DH-structure and window layer on the DH-structure effect an extremely high luminescent efficiency in this type of LED.

![Figure 8. AlInGaP technology](image4)
White LED

In general white light is a mixture of the 3 basic colors red, green and blue. A cost effective solution is white light out of only one chip by using the physical principle of luminescence conversion. A high brightness InGaN-based LED chip, mounted in the reflector cup is covered by a luminescence converter consisting of an inorganic phosphor material dissolved in Silicon, while the whole system is embedded in transparent epoxy resin. Part of the blue light is absorbed by a YAG–Phosphor converter and emitted at a longer wavelength. The complementary colors blue and yellow mix to form white.

LED Characteristics

The most important characteristics of the LEDs dealt with here are summarized in table 1. The emission of LEDs is almost monochromatic and can be characterized by a peak wavelength (column 4) and a spectral half bandwidth (column 6). The lowest spectral half bandwidth is generated by LEDs with direct band-to-band recombination, while other mechanisms and material inhomogeneities lead to wider emission. Here, it is evident that the efficiency drops as the wavelength is reduced.

Liquid-phase elements generally have a higher efficiency than comparable vapor-phase elements. For applications in which a Si detector is to be used as a receiver, for example, the emitted radiated power $P_e$ is important. If, however, the receiver is the human eye, the light flux $V$ is decisive.

Figure 10 shows the sensitivity of the human eye in accordance with DIN 5031. The maximum value is 683 lm/W at 555 nm. Green LEDs are close to this maximum value, while the curve for red emission drops rapidly. An orange LED (630 nm), for example, appears approximately 5 times brighter than a red LED (660 nm) at the same efficiency.

Electrically, LEDs are ordinary PN diodes (except for GaN). The most important parameter for normal operation is the forward voltage $V_F$. (Table 1, third column from the right) where the numerical value in $V$ corresponds approximately to the bandgap of the semiconductor used. The speed of LEDs is characterized by their switching times (last columns); red LEDs made of direct materials are fastest, while indirect types are considerably slower due to the special recombination mechanism. Generally, LEDs are robust and their lifetimes (more than $10^5$ hours) are more than sufficient for practically all applications.
Due to the rapid current rise in the forward direction, LEDs are always connected in series with a current limiting element. Figure 11 shows how the working point is set with a series resistor. If the supply voltage varies greatly, a constant current source is used. Digital displays and similar devices are often operated in multiplex mode. The seven data lines carry the information for the digits in a time-staggered manner. Each LED is operated for one-quarter of the time with four times the current in order to achieve the same intensity as in continuous operation. In displays with larger numbers of LEDs, it is advisable to reduce the number of driver stages and connecting leads. Due to the diode characteristics of LEDs, a large number of LEDs can be operated with only a few leads if the circuit is designed accordingly.

Special Notes and Conversion Diagrams

a) At standard illuminant A:
   1 klx = 6.1 mW/cm² or 1 mW/cm² = 164 lx
b) At 555 nm it is valid: 683 lm = 1 W
   634.5 lm/ft² = 1 mW/cm²
c) 1 lumen/ft² = 1 footcandle
   4 π candlepower = 1 lumen (lm)
