DESCRIPTION

The Si9913 is a dual MOSFET high-speed driver with break-before-make. It is designed to operate in high frequency dc-dc switchmode power supplies. The high-side driver is bootstrapped to handle the high voltage slew rate associated with “floating” high-side gate drivers. Each driver is capable of switching a 3000-pF load with 60-ns propagation delay and 25-ns transition time. The Si9913 comes with internal break-before-make feature to prevent shoot-through current in the external MOSFETs. A synchronous enable pin is used to

enable the low-side driver. When disabled, the OUT_L is logic low.

The Si9913 is available in both standard and lead (Pb)-free 8-pin SOIC packages for operation over the industrial operation range (-40°C to 85°C).

THEORY OF OPERATION
Break-Before-Make Function

The Si9913 has an internal break-before-make function to ensure that both high-side and low-side MOSFETs are not turned on at the same time. The high-side drive (OUT_H) will not turn on until the low-side gate drive voltage (measured at the OUT_L pin) is less than V_{B_{BM}}, thus ensuring that the low-side MOSFET is turned off. The low-side drive (OUT_L) will not turn on until the voltage at the MOSFET half-bridge output (measured at the V_S pin) is less than V_{B_{BM}}, thus ensuring that the high-side MOSFET is turned off.

Under Voltage Lockout Function

The Si9913 has an internal under-voltage lockout feature to prevent driving the MOSFET gates when the supply voltage (at V_{DD}) is less than the under-voltage lockout specification (V_{UVL}). This prevents the output MOSFETs from being turned on without sufficient gate voltage to ensure they are fully on. There is hysteresis included in this feature to prevent lockout from cycling on and off.

Bootstrap Supply Operation (see Functional Block Diagram)

The power to drive the high-side MOSFET (Q2) gate comes from the bootstrap capacitor (C_{BOOT}). This capacitor charges through D1 during the time when the low-side MOSFET is on (V_S is at GND potential), and then provides the necessary charge to turn on the high-side MOSFET. C_{BOOT} should be sized to be greater than ten times the high-side MOSFET gate capacitance, and large enough to supply the bootstrap current (I_{BOOT}) during the high-side on time, without significant voltage droop.

Synchronous Enable

The synchronous enable pin serves to enable and disable the drive to the low-side MOSFET gate. With SYN high, the low-side MOSFET is driven on and off in antiphase with the high-side MOSFET to form a synchronous rectifier. This improves efficiency at high load currents because the flyback current is carried by the MOSFET, thus eliminating the diode

drop. With SYN low, the low-side MOSFET is held off all the time. This is particularly useful for discontinuous operation under light load or pulse skipping mode, where there is a long off time, because it prevents current flowing back from the output to ground during the off time.

Layout Considerations

There are a few critical layout considerations for these parts. Firstly, the IC must be decoupled as closely as possible to the power pins. Secondly the IC should be placed physically close to the high- and low-side MOSFETs it is driving. The major consideration is that the MOSFET gates must be charged or discharged in a few nanoseconds, and the peak current to do this is of the order of 1 A. This current must flow from the decoupling and bootstrap capacitors to the IC, and from the output driver pin to the MOSFET gate, returning from the MOSFET source to the IC. The aim of the layout is to reduce the parasitic inductance of these current paths as much as possible. This is accomplished by making these traces as short as possible, and also running trace and its current return path adjacent to each other.
